ABSTRACT

We performed a combined analysis of mitochondrial (mt) DNA control region sequence and four polymorphic microsatellite (ms) DNA loci to estimate the genetic differentiation and genetic structure among chum salmon populations in the Pacific Rim. Nucleotide sequence analysis of the mtDNA control region revealed 22 variable nucleotide sites, which defined a total of 32 haplotypes of three clades (A, B and C), in more than 4,200 individuals representing 96 populations including newly collected 20 populations from North America. The occurrence of haplotypes was in keeping with our previous observations, in that clade A and C haplotypes characterized Asian populations and clade B haplotypes distinguished North American populations. The analysis of molecular variance and pairwise population F_{ST} estimation further advocate our previous findings, which include the highest genetic variation in the Japanese populations, strong structuring among Japanese, Russian and North American populations, and a substantial geographic structuring among local populations within regions. Similar population genetic analyses with msDNA using more than 1,100 individuals from 24 populations of Japan (14) and North America (10) also disclosed a greater genetic diversity in the populations of Japan than North America and a distinct genetic differentiation between and within geographical groups of populations. The observed congruence in the results from mtDNA and msDNA analyses suggests that the battery of two DNA markers will become useful for construction of the baseline for better genetic stock identification of mixed chum salmon populations in high seas.

INTRODUCTION

Chum salmon have received considerable attention due to their wide geographic distribution in the Pacific Rim (Salo 1991) and high commercial importance. Stock identification of chum salmon in mixed aggregations in high seas is therefore a fundamental international issue. Recently developed molecular techniques are expected to provide a powerful means with an increased accuracy and resolution to reveal genetic variation in salmon populations. However, sufficient information has not yet been accumulated to conclude which DNA markers improve discrimination among populations and whether any variation in the utility of different markers exists at different geographic scale of analysis.

Recently, Sato et al. (2001; 2004a) detected greater amount of variation in the mtDNA control region by nucleotide sequence analysis than the variation observed by a previous RFLP

analysis (Park et al. 1993). The mtDNA sequence analysis using more than 3,000 fish representing 76 chum salmon populations in the Pacific Rim revealed a clear geographic structuring among Japan, Russia and North America and among local populations within regions (Yoon et al. 2004). These findings suggest the possibility of mtDNA sequence variation to become a competent marker for genetic stock identification (GSI) of chum salmon (Sato et al. 2004b, Yoon et al. 2004), if the comprehensive baseline data could be established without gaps in collection sites along the Pacific Rim.

Microsatellite DNA with tandem repeats of 2 to 4 base short motifs is a class of highly polymorphic nuclear DNA markers that are suitable for studies on the level of intraspecific genetic diversity and population structure (Bruford & Wayne 1993). A variety of polymorphic msDNA loci have so far been developed for the population analysis of Pacific salmon, with a hope to utilize them as a tool of GSI (Beacham and Candy 2005, Habicht et al. 2005).

In this study, we recruited 20 additional chum salmon populations from North America in the mtDNA sequence analysis to see if more sequence variation could be detected to improve estimation of genetic diversity and population structure in the Pacific Rim. Also, msDNA analysis was performed with four polymorphic loci (Abe et al. 2002) using Japanese and North American populations to compare the genetic features obtained from mtDNA analysis.

MATERIALS AND METHODS

Sampling profile

Liver, fins, or muscle samples of chum salmon were collected from 976 individuals from 20 North America populations for the mtDNA analysis (Table 1 and Figure 1). For the msDNA analysis, 1,186 individuals of 24 populations from Japan (14 populations) and North America (10 populations of Northwest, Southcentral Alaska, and Alaska Peninsula) were used, all of which were the same samples as used for the mtDNA analysis. Liver samples were stored at -80°C , and fins and muscle samples were kept in ethanol at room temperature until DNA extraction.

Mitochondrial and microsatellite DNA analyses

DNA was isolated with conventional phenol-chloroform method (Sambrook et al. 1989) from the stored specimens as in our previous studies (Sato et al. 2001, 2004). Approximately 500 bp in the variable position of the 5' end of the mtDNA control region was sequenced with an ABI PRISM 3130 xl genetic analyzer (Applied Biosystems) (Sato et al. 2001), in addition to the analysis using the newly developed DNA microarray hybridization method (Moriya et al. 2004).

Four polymorphic msDNA loci (OKM4, OKM5, OKM7 and OKM8) (see also Abe et al. 2002) were examined by the polymerase chain reaction (PCR) amplification, in which one primer of each primer set was labeled with the fluorescent dyes: FAM, NED, NIC or PET. The optimization of PCR conditions determined for chum salmon were one min pre-denature at 95°C , followed by 30 cycles of denaturation at 95°C for 15 sec, annealing at 57°C (except for OKM5 at 55°C) for 15 sec, and extension at 72°C for 60 sec. The PCR products were analyzed on an ABI PRISM 3130XL Genetic analyzer (Applied Biosystems).

Population genetic data analysis

Departure from Hardy-Weinberg equilibrium (HWE) and Genotype frequency at each locus were assessed in each population using Genepop version 3.4 program packages. Gene diversity according to Nei (1987) for the msDNA and pairwise population F_{ST} estimation with mtDNA were performed using the Arlequin version 2.000 program package (Schneider et al.

2000). A neighbor-joining tree inferred from msDNA data was constructed with NEIGHBOR and the consensus tree was generated using CONSENSUS in PHYLIP version 3.5c software (Felsenstein 1993). Other population genetic parameters such as haplotype and nucleotide diversities with mtDNA also were estimated using the Arlequin program. In order to assess the extent of genetic divergence at different levels of geographic hierarchy, the overall molecular variance was partitioned into components corresponding to the population divergence within and among regions by the analysis of molecular variance model (AMOVA; Excoffier et al. 1992) using the above Arlequin program for both mtDNA and msDNA analyses.

RESULTS

Mitochondrial DNA analysis

Estimation of the 481 bp sequence in the 5' variable portion of chum salmon mtDNA control region disclosed 22 variable sites in 4,243 individuals from 96 populations including previously analyzed 76 populations (1-76) (Yoon et al. 2004) and additional 20 North American populations (77-96) (Table 1 and Figure 1), which defined a total of 32 haplotypes including the previously defined 30 haplotypes (Sato et al. 2004) and newly identified two haplotypes of clade B (Table 2) from WHN Hatchery (82, 83) and Marten River (85) in the 20 additional populations (Table 3).

The number of haplotypes in North American populations was apparently less than that of populations in Japan and Russia even after addition of the 20 additional populations (Yoon et al. 2004; also see Table 3). The North American populations exhibited no clade A haplotypes, and one clade C haplotype occurred in only Toklet River (77) (see Table 3 and Figure 1).

Two novel haplotypes of clade B were designated to B-11 and B-16 by nucleotide variation (Table 2) and on a parsimony network (Figure 2). Therefore, the 7 haplotypes reported in the previous study (Sato et al. 2004) were changed as follows: B-11 to B-12, B-12 to B-13, B-13 to B-14, B-14 to B-15, B-15 to B-17, B-16 to B-18 and B-17 to B-19, respectively. Nucleotide divergence and the number of net nucleotide substitution per sites between clade A and C was lower than those between A and B and between B and C, suggesting a closer genetic kinship between A and C than between B and C and between A and B lineages (Table 4).

The observed haplotype distribution in the present 20 populations from North America was mostly the same as those found in our previous observations (Sato et al. 2004) and further advocated a geographic association of haplotypes, in that clade A and C haplotypes characterized Asia and Russian populations and clade C haplotypes distinguish Alaskan population.

Haplotype diversity was highest in the populations of Japan (0.607 ± 0.001), followed by those of Russia (0.359 ± 0.001) and North America (0.174 ± 0.001), whereas nucleotide diversity was nearly similar in the Japanese (0.0021) and Russian populations (0.0017), but lower in the North American populations (Table 5). These findings suggest a greater genetic variation in the populations of Japan than those of Russia and North America.

As shown in Table 6, pairwise F_{ST} estimates were greater between Japan and North America (0.667 to 0.905) than between Japan and Russia (0.013 to 0.883) or between Russia and North America (0.000 to 0.867). The AMOVAs (Table 7) revealed the following population structure in the Pacific Rim chum salmon populations; very strong geographic structuring among Japan, Russia, and North America (68.7% of the total variance, $p < 0.001$, Analysis I), as compared with the average extent of structuring among populations within each geographic group (5.0% of the total variance), similar level of population structuring among three regional groups in Japan (7.8% of the variance, $p < 0.001$, Analysis II), among five regional groups in North America (2.5% of the variance, $p < 0.001$, Analysis IV), and among six regional groups of Russia (29.0% of the variance, $p < 0.001$, Analysis III). These results suggest more definite

geographic structuring among regional groups than our previous study (Yoon et al. 2004).

Microsatellite DNA analysis

The number of alleles per locus across all populations was highest at the OKM8 locus with 16 in the Chitose River and lowest at the OKM7 with 1 in the Upper Nushagak River and Donjek River. The gene diversity per population was ranged from 0 at the OKM7 in two North American populations to 0.887 at the OKM4 in one Japanese population. Also, the expected heterozygosity within Japanese populations (0.262-0.889) was higher than North American populations (0-0.682) (Table 8). These findings suggest greater genetic variation in the populations of Japan than North America.

A total number of 79 alleles were observed across the four loci, which ranged from 16 alleles at the OKM5 to 29 alleles at the OKM8 over all populations, and the observed heterozygosity for all populations ranged from 0.277 at the OKM7 to 0.681 at the OKM8 (Table 8), reflecting the large difference in number of alleles and between these loci.

A deviation from HWE assessed by Markov chain procedure ($P < 0.01$) was observed in the Tokoro River (early run), Nishibetsu River, Gakko River, Kwethluk River and South fork kuskokwin River at the OKM8 locus. The deviation was also observed in the Tokachi River and Tanana River at the OKM4, and the Uono River, South fork kuskokwin River and Pelly River at the OKM5. Significant disequilibrium was found in the Chiginagak River at all of the examined microsatellite loci (Table 8).

The populations examined were clustered using the neighbor-joining method based on Nei's genetic distance (Figure 3). The population consensus tree clearly separated all Japanese populations from the 10 North American populations, although the Chiginagak River in the Alaska Peninsula was clearly separated from the other North America populations with high bootstrap support (100%).

AMOVAs (Table 9) indicated that most variation occurred within populations with the high variability (more than 87%) of all the microsatellite loci used. Even though msDNA failed to show genetic differentiation among regional groups in Japan ($P > 0.05$), there was significant structuring among Japan and North America ($P < 0.001$) and among regional groups in North America, i.e. Northwest, Southcentral Alaska, and Alaska Peninsula.

DISCUSSION

In the present study, recruitment of 20 North American populations of chum salmon for mtDNA sequence analysis resolved 22 variable positions in about 500 bp nucleotide sequence at the 5' end of the control region (Table 2), which defined a total of 32 haplotypes in more than 4,200 individuals representing 96 populations of chum salmon in the Pacific Rim. Two novel haplotypes were both clade B lineage, but the haplotype and nucleotide diversities in North America remained the lowest among three regions. Geographic association of haplotypes and population genetic features with the present mtDNA data also were in keeping with our previous observations (Sato et al. 2004, Yoon et al. 2004).

The AMOVAs and pairwise F_{ST} estimates with the present mtDNA data revealed clear geographic structuring in the Pacific Rim chum salmon populations among and within Japan, Russia, and North America. Incorporation of 20 North American populations thus provided an increased resolution in the geographic differentiation among three regional groups of populations (68.7%, $P < 0.001$, Table 7) as compared with the previous estimation (56.8%, $P < 0.001$) by Yoon et al. (2004). These results suggest that the detailed sampling design, particularly with recruitment of more North American and Russian populations, is essential to improvement of genetic resolution for geographic structure of Pacific Rim chum salmon populations.

The present msDNA analysis revealed substantial genetic diversity in the examined populations, providing fairly good discrimination among regional populations of Japan and North America. In North America, three regional groups were more clearly structured (8.27%, $P < 0.001$ and $\Phi = 0.08$) than did by mtDNA (2.1%, $P < 0.001$ and $\Phi = 0.02$), as shown by AMOVA (Tables 7 and 9). Estimates of the extent of population differentiation by msDNA and mtDNA are mostly congruent, although F_{ST} values by msDNA (data not shown) seems generally low compared with those by mtDNA (see Abe et al. 2002). It is unknown, however, for the reason of the failure to demonstrate the geographic structure in Japan by AMOVA (Table 9) with four msDNA loci. Increased number of polymorphic loci may be worth attempt to confirm the present results.

Based on the high degree of genetic divergence among and within geographical groups of populations revealed by the present mtDNA and msDNA analyses, a battery of these two DNA markers seems to provide better resolution in the divergence estimation than that expected from the previous allozyme and other DNA analyses. Both DNA markers here concerned should therefore be applied in mixed samples of salmon aggregations in high seas, to evaluate the discriminative potential in GSI of chum salmon. In parallel with such an attempt, continuous efforts must be made to establish the baseline data with both markers, which is essential to substantiation of marker utility in mixed-stock identification of Pacific salmon.

Table 7. Results of the hierarchical analyses of molecular variance based on mtDNA for chum salmon. The percentage of variance (%), probability estimated from permutation (P), and the F-statistics (Φ) are given at hierarchical level (Excoffier et al. 1992).

| Variance component | % | P | Φ |
|--|-------|--------|--------|
| Analysis I | | | |
| Among three regional groups (Japan, Russia, and North America) | 68.7 | <0.001 | 0.68 |
| Among populations within groups | 5.0 | <0.001 | 0.16 |
| Within populations | 26.25 | <0.001 | 0.74 |
| Analysis II | | | |
| Among three regional groups in Japan (Hokkaido, Sea of Japan coast in Honshu, and Pacific Ocean coast in Honshu) | 7.8 | <0.001 | 0.08 |
| Among populations within groups | 3.2 | <0.005 | 0.03 |
| Within populations | 89.0 | <0.001 | 0.11 |
| Analysis III | | | |
| Among six regional groups in Russia (Kamchatka, Sakhalin, Primorye, Megadan, Semovodka, and Amur) | 29.0 | <0.001 | 0.29 |
| Among populations within groups | 1.9 | <0.005 | 0.27 |
| Within populations | 69.1 | <0.001 | 0.31 |
| Analysis IV | | | |
| Among five regional groups in North America (Northwest Alaska, Alaska Peninsula/Southcentral Alaska, Southeast Alaska, British Columbia, and Washington) | 2.1 | <0.001 | 0.02 |
| Among populations within groups | 4.1 | <0.001 | 0.04 |
| Within populations | 93.8 | <0.001 | 0.06 |

Table 8. Range of allele size (S), total number of alleles (A_T), the number of samples (N), observed (H_O), expected (H_E) heterozygosity and gene diversity (H_S) by locus for 24 chum salmon populations.

*Departure from Hardy-Weinberg equilibrium by Markov chain procedure ($P < 0.01$)

Table 9. Results of the hierarchical analyses of molecular variance based on msDNA for chum salmon. The percentage of variance (%), probability estimated from permutation (P), and the F-statistics (Φ) are given at hierarchical level (Excoffier et al. 1992).

| Variance component | % | P | Φ |
|--|-------|--------|--------|
| Analysis I | | | |
| Among regional groups (Japan and North America) | 9.93 | <0.001 | 0.10 |
| Among populations within groups | 2.73 | <0.001 | 0.03 |
| Within populations | 87.34 | <0.001 | 0.13 |
| Analysis II | | | |
| Among regional groups in Japan (Hokkaido, Sea of Japan coast in Honshu, and Pacific Ocean coast in Honshu) | 0.44 | >0.05 | 0.004 |
| Among populations within groups | 1.52 | <0.001 | 0.02 |
| Within populations | 98.04 | <0.001 | 0.02 |
| Analysis III | | | |
| Among regional groups in North America (Northwest Alaska, Southcentral Alaska, and Alaska Peninsula) | 8.27 | <0.001 | 0.08 |
| Among populations within groups | 2.54 | <0.001 | 0.03 |
| Within populations | 89.19 | <0.001 | 0.11 |
